ABSTRACT

Cancer genotyping has identified a large number of putative tumor suppressor genes. Carcinogenesis is a multi-step process, however the importance and specific roles of many of these genes during tumor initiation, growth and progression remain unknown. Here we use a multiplexed mouse model of oncogenic KRAS-driven lung cancer to quantify the impact of forty-eight known and putative tumor suppressor genes on diverse aspects of carcinogenesis at an unprecedented scale and resolution. We uncover many previously understudied functional tumor suppressors that constrain cancer in vivo. Inactivation of some genes substantially increased growth, while the inactivation of others increases tumor initiation and/or the emergence of exceptionally large tumors. These functional in vivo analyses revealed an unexpectedly complex landscape of tumor suppression that has implications for understanding cancer evolution, interpreting clinical cancer genome sequencing data, and directing approaches to limit tumor initiation and progression.

STATEMENT OF SIGNIFICANCE

Our high-throughput and high-resolution analysis of tumor suppression uncovered novel genetic determinants of oncogenic KRAS-driven lung cancer initiation, overall growth, and exceptional growth. This taxonomy is consistent with changing constraints during the life history of cancer and highlights the value of quantitative in vivo genetic analyses in autochthonous cancer models.
INTRODUCTION

Cancer initiation and development is a multi-step process driven in large part by cancer cell-intrinsic alterations (1). Over the past several decades, cancer genome sequencing has contributed to our understanding of the genetic drivers of cancer and identified a large number of putative tumor suppressor genes (2-8). However, genome sequencing data is insufficient to determine the importance of these genes during various stages of carcinogenesis (9). The nature and frequency of genomic alterations also provide limited insight into the modes of action of putative tumor suppressor genes, underscoring the importance of functional genomics in elucidating gene function (10,11).

Tumor suppressors regulate many different pathways and cellular processes. Assessing their impact on tumor initiation and each step of cancer development not only distinguishes driver from passenger genes but also highlights different pathways and processes that constrain carcinogenesis across the course of the disease (12,13). Thus, in vivo functional genomic approaches are critical for understanding cancer evolution (14-16), interpreting clinical cancer genome sequencing data (17,18), and directing precision medicine approaches (19,20).

In vivo cancer models in which tumor initiation and growth occurs entirely within the autochthonous environment are uniquely tractable systems to uncover gene function (21). The integration of CRISPR/Cas9 somatic genome editing into genetically engineered mouse models of human cancer has facilitated the rapid analysis of gene function in vivo (22-25). Recently, the combination of somatic CRISPR-based genome editing with tumor barcoding and high-throughput barcode sequencing (Tuba-seq) has greatly increased the scale and precision of these in vivo approaches (26,27). These types of approaches can quantify the impact of many engineered genomic alterations on cancer growth in vivo in a multiplexed manner (12,26-28).
Here we integrate multiple critical advances in our Tuba-seq pipeline and quantify the roles of a broad range of diverse putative tumor suppressors across multiple facets of carcinogenesis. By uncovering the extent to which different tumor suppressors govern tumor initiation, growth and acquisition of altered phenotypes across time, we uncover an unexpectedly complex taxonomy of tumor suppression across the life history of oncogenic KRAS-driven lung cancer.

RESULTS

Prioritization of candidate tumor suppressor genes

To characterize the functional landscape of tumor suppression, we selected 48 known and putative tumor suppressor genes to investigate using Tuba-seq in a model of oncogenic KRAS-driven lung cancer (Fig. 1A; Methods). These genes were chosen based on multiple criteria including their mutational frequency in lung adenocarcinoma from TCGA, GENIE, and TRACERx datasets, their mutational frequency in pan-cancer genomic data, and the consistency of their mutational profiles with tumor suppressor activity (Fig. 1A and B; Supplementary Fig. S1A-E and Table S1)(2,4-7). We also considered their putative tumor-suppressive function in other cancer types as well as their molecular functions (Supplementary Fig. S2A and B)(8,29,30). Our candidate genes vary greatly in their mutation frequency and co-occurrence with oncogenic KRAS alterations (Supplementary Fig. S1C-E). Importantly, these genes include well-studied tumor suppressors as well as genes for which there is very limited evidence supporting a role in constraining any aspect of carcinogenesis (Supplementary Fig. S3A and B).
Quantitative analysis uncovers diverse tumor suppressors with distinct abilities to constrain tumor growth in vivo.

To determine the impact of inactivating each candidate tumor suppressor gene on carcinogenesis in vivo, we used Tuba-seq to quantify the tumor size profiles after inactivation of each gene (Supplementary Fig. S4A). We generated at least two Lenti-sgRNA/Cre vectors with distinct sgRNAs targeting each gene and five Lenti-sgInert/Cre negative control vectors (102 total vectors; Fig. 1C; Supplementary Table S2). Each vector contains a two-component sgID-BC, where the sgID uniquely identifies the sgRNA and the diverse random 20-nucleotide barcode (BC) uniquely labels each clonal tumor. We generated each lentiviral vector separately and pooled them to generate a highly multiplexed vector pool (Lenti-sgTS102/Cre; Fig. 1C; Methods). We initiated lung tumors with this pool in \( \text{Kras}^{\text{LSL-G12D}/+}; \text{R26}^{\text{LSL-Tom}/-}; \text{H11}^{\text{LSL-Cas9}} \) (KT;H11\text{LSL-Cas9}) mice and Cas9-negative control Kras\(^{\text{LSL-G12D}/+}; \text{R26}^{\text{LSL-Tom}/-} \) (KT) mice. These Cas9-negative mice are necessary to confirm that all vectors have little impact on tumor growth in the absence of Cas9 and to calculate genotype-specific effects on tumor number (see below).

Fifteen weeks after tumor initiation, KT;H11\text{LSL-Cas9} mice had visibly larger tumors than KT mice (Fig. 1D). We extracted DNA from bulk tumor-bearing lungs and used Tuba-seq to quantify overall tumor burden and the sizes of each tumor, of each genotype, in each mouse. KT;H11\text{LSL-Cas9} mice had ~10-fold higher total neoplastic cell number and proportionally increased total lung weight (Fig. 1E). Initial analysis of the impact of each sgRNA on tumor burden (a metric of the relative number of neoplastic cells in all tumors of the same sgRNA) highlighted many genes as functional tumor suppressors. Even this relatively crude metric, which does not incorporate the per-tumor resolution of Tuba-seq, uncovered genes where both sgRNAs increased tumor burden (Fig. 1F). To investigate which aspects of carcinogenesis are regulated...
by putative tumor suppressor genes, we calculated multiple summary statistics. We applied our
experimental design to identify tumor suppressor genes that normally limit overall tumor growth,
tumor initiation, and the emergence of exceptionally large tumors (Fig. 1C; Supplementary Fig.
S4B, S4C; Methods).

Many diverse tumor suppressor genes increased overall tumor growth

The ability of Tuba-seq to quantify the number of neoplastic cells in thousands of tumors
of each genotype allowed us to precisely assess their impact on tumor growth with greater
precision than previous approaches. We calculated two metrics of tumor growth from the
distribution of tumor sizes to uncover the effect of inactivating each tumor suppressor on overall
tumor growth (tumor sizes at defined percentiles within the tumor size distribution and log-
normal mean, Methods; Supplementary Fig. S4B). As expected, tumors initiated with each
Lenti-sgRNA/Cre vector in control Cas9-negative KT mice had very similar tumor size profiles,
suggesting that our pipeline is free from bias and false-positive signals (Supplementary Fig.
S5A). Consistent with previous Cre/lox and CRISPR/Cas9-based mouse models (22,26,31-34),
inactivation of Stk11/Lkb1, Pten, Setd2, and Nf1 in tumors in KT;H11Lsl-Cas9 mice greatly
increased tumor growth (Fig. 2A-C; Supplementary Fig. S5B). Importantly, inactivation of
STAG2, a cohesin complex component, increased tumor growth to a comparable extent as
inactivation of those well-established tumor suppressors (Fig. 2A-C; Supplementary Fig. S5B).
Inactivation of 14 other genes, including Cdkn2c, Cmtr2, Rb1, Rnf43, Tsc1, and Rbm10,
significantly increased tumor growth (Fig. 2A-C; Supplementary Fig. S5). These 14 genes
include not only well-established tumor suppressors such as Rb1 and Cdkn2a, but also many
genes that have not been previously considered functional tumor suppressors in lung
adenocarcinoma or cancer in general. For example, the effects of inactivating Cmtr2 and Rnf43 were particularly dramatic and unexpected (Fig. 2B). CMTR2 is the sole cap2 2’-O-ribose methylase that modifies the 5’-cap of mRNAs and small nuclear RNAs and is mutated in ~2.2% of lung adenocarcinomas and 1.4% of all cancers (7,35)(Supplementary Table S1). No previous studies have investigated its function in cancer, and no commercial or academic cancer gene sequencing panels include CMTR2 (Supplementary Fig. S3A and B). RNF43 is a transmembrane E3 ubiquitin ligase that targets Wnt receptors for lysosomal degradation (36).

RNF43 is frequently mutated across multiple cancer types, including in colorectal and pancreatic adenocarcinoma, where RNF43 deficiency has been shown to sensitize cancer cells to porcupine inhibitors (37,38). Thus, our broad survey pinpointed multiple novel functional tumor suppressors in oncogenic KRAS-driven lung cancer and revealed commonality among cancer subtypes.

**STAG2 is a novel functional tumor suppressor**

From our initial analysis of overall tumor growth suppression, STAG2 emerged as a particularly interesting and novel suppressor of lung tumor growth. STAG2 is mutated in ~4% of lung adenocarcinomas and cohesin complex components are altered in ~10% of lung adenocarcinomas (Supplementary Fig. S6A, S6B and Table S1). STAG2 has been implicated as a tumor suppressor in bladder cancer, regulates lineage-specific genes in acute myeloid leukemia, and is mutated across diverse cancer types (39-42). However, no previous studies have suggested STAG2 as a critical suppressor of lung cancer growth. To further investigate the tumor-suppressive effect of STAG2, we initiated lung tumors in KT and KT;H11LSL-Cas9 mice with individual Lenti-sgInert/Cre and Lenti-sgStag2/Cre vectors (Supplementary Fig. S7A).
Relative to control cohorts, Stag2 inactivation dramatically increased tumor burden (Supplementary Fig. S7B-E). Inactivation of Stag2 in lung tumors in KT;H11^{LSL-Cas9} mice also significantly reduced long-term survival, consistent with its tumor growth-suppressive function (Supplementary Fig. S7F).

To further characterize STAG2-mediated lung tumor growth suppression, we assessed tumor growth in KT mice with Cre/lox-mediated inactivation of Stag2 (Fig. 3A). Stag2 is located on the X-chromosome, thus both heterozygous and homozygous Stag2 deletion in female mice and hemizygous Stag2 deletion in male mice generated tumors that lacked STAG2 protein (Fig. 3B and C). Stag2 inactivation dramatically increased lung tumor burden, and mice with Stag2-deficient tumors had markedly shorter overall survival (Fig. 3D-G). Stag2-deficient and proficient lung tumors were atypical adenomatous hyperplasias, adenomas, and early adenocarcinomas that were uniformly NKX2-1/TTF1-positive. Interestingly, some Stag2-deficient tumors had nuclear palisading and were histologically distinct from the tumors that developed in control KT mice (Supplementary Fig. S7G-I). STAG2 inactivation in other cancer- and cell-types is associated with chromosomal instability (43,44), increased DNA damage (45,46), and activation of MEK/ERK or cGAS/STING signaling (47,48). However, immunohistochemistry and analysis of canonical target genes suggest that these mechanisms are unlikely to be major drivers of the increased growth in Stag2-deficient lung cancer (Supplementary Fig. S8A-E). Thus, further work will be necessary to determine the molecular mechanisms of tumor suppression driven by STAG2.

Finally, to further characterize the expression of STAG2 in lung cancer, we perform immunohistochemistry for STAG2 on 479 human lung adenocarcinomas. About 20% of tumors were low or negative for STAG2 protein, suggesting that an even larger fraction of lung
adenocarcinomas may be driven by alterations in this pathway (Fig. 3H). Interestingly, STAG2-
low/negative tumors were often more poorly differentiated and advanced human lung adenocarcinomas (Fig. 3I).

Additional tumor-suppressive effects emerge at later time points

To gain further insights into the dynamics of tumor suppression in lung cancer, we assessed tumor suppressor gene function at a later timepoint after tumor initiation. We reasoned that allowing tumors to grow for a longer period of time might uncover greater magnitudes of growth-suppression for genes that initially had modest effects and could highlight additional tumor suppressors that play more important roles only at later stages of tumor growth. To allow mice to survive for a longer period of time after tumor initiation, we generated a second pool of Lenti-sgRNA/Cre vectors, which excluded those targeting Lkb1, Pten, Setd2, Nf1, p53, Stag2, Cdkn2c and Rb1 that collectively accounted for more than half of the total tumor burden (Lenti-sgTS85/Cre; Fig. 4A). We initiated tumors in KT;H11LSL-Cas9 mice with a titer of Lenti-sgTS85/Cre that would allow them to survive for 26 weeks while maximizing tumor number to achieve reasonable statistical power (Fig. 4A; Supplementary Fig. S9A; Methods). As controls, we also initiated tumors with Lenti-sgTS85/Cre pool in KT;H11LSL-Cas9 and KT mice and analyzed them after 15 weeks (Fig. 4A).

After 26 weeks of tumor growth, inactivation of Cdkn2a, Dnmt3a, Cmtr2, Kdm6a and Ncoa6 significantly increased tumor burden (Fig. 4B). Furthermore, inactivation of Rbm10, Cmtr2, Rnf43 and Tsc1 also still increased tumor sizes at defined percentiles of the distribution as well as the log-normal mean tumor size at this later time point (Supplementary Fig. S9B).

These results confirm the tumor-suppressive function of these genes. Importantly, inactivation of
several other genes that had marginal to no effects on tumor sizes after 15 weeks of tumor
growth, including Keap1, Kdm6a, Ncoa6, Cdkn2a, Dnmt3a and Dot1l, broadly increased tumor
sizes after 26-weeks of tumor growth (Fig. 4C-F). Thus, analysis of growth metrics at multiple
time points after tumor initiation can provide temporal resolution of tumor suppressor gene
effects.

Tuba-seq captures additional aspects of tumor suppressor gene function

In addition to uncovering tumor suppressor genes that limit overall growth, our methods
can quantify other aspects of cancer initiation and progression impacted by these genes and
pathways. The relative tumor burden induced by each Lenti-sgRNA/Cre vector was mostly
consistent with the growth effects uncovered using tumor sizes at defined percentiles
(Supplementary Fig. S10A). However, the effects of inactivating some genes on relative tumor
burden were disproportionately large (Supplementary Fig. S10A and B). For example, p53 was
clearly a tumor suppressor based on relative tumor burden but p53 inactivation did not greatly
increase overall tumor growth as assessed by log-normal mean or tumor sizes up to the 95%
percentile tumor (Supplementary Fig. S10A). Inactivation of several other genes also had much
more significant and dramatic effects on relative tumor burden than on tumor sizes
(Supplementary Fig. S10B and C). These disproportionate increases in relative tumor burden
could be driven by genotype-specific increases in tumor number and/or the sizes of the very
largest tumors, neither of which are captured well by log-normal mean or tumor sizes at defined
percentile of the tumor size distribution.

Many tumor suppressors constrain tumor initiation
Our experimental design, in which we initiated tumors in cohorts of $KT;H1^{LSL-Cas9}$ and $KT$ mice with the exact same pool of lentiviral vectors, enabled us for the first time to use Tuba-seq to uncover the impact of each putative tumor suppressor gene on tumor initiation and very early oncogenic KRAS-driven epithelial expansion (Supplementary Fig. S4C and Methods). The genetic alterations that drive the development of very early epithelial expansions are poorly understood, yet these events influence tumor incidence and set the stage for all subsequent events during cancer evolution. In vivo mouse models are particularly well suited to study the effects of genetic alterations on these early events.

Fifteen weeks after tumor initiation, inactivation of many genes including $Lkb1$, $Setd2$, and $Stag2$, which had some of the most dramatic effects on tumor growth, did not increase tumor number (defined as the number of clonal expansions with more than 200 cells; Fig. 5A; Supplementary Fig. S4C and Methods). However, $Pten$ inactivation increased tumor number by ~4-fold, suggesting that at least three-quarters of epithelial cells expressing oncogenic KRAS$^{G12D}$ fail to expand beyond a very small size if at all (Fig. 5A and B). $Tsc1$ inactivation also increases tumor number, albeit to a lesser extent, consistent with TSC1 suppressing mTOR downstream of PI3K (49). Inactivation of $Nf1$, $Rasa1$, and $p53$ also increased tumor number, thus implicating several signaling pathways in the earliest stages of lung tumor development (Fig. 5A). Strikingly, inactivation of four members of the COMPASS complex ($Kdm6a$, $Ncoa6$, $Kmt2c/Mll4$ and $Kmt2d/Mll3$)(50,51) all increased tumor number (Fig. 5A). The importance of histone H3K4 methylation mediated by this complex is further substantiated by the mutation of at least one member of this complex in 8.9-32.5% of human lung adenocarcinoma (Fig. 5C and D)(2). Importantly, genes that limit tumor initiation and those that constrain tumor growth are
often independent, suggesting that these facets of tumor suppression can represent distinct
functions (Supplementary Fig. S11A).

Analysis of the effect of each genotype on tumor number in mice with tumors initiated
with the Lenti-sg85/Cre pool (at both 15 and 26-weeks after tumor initiation) provided us with
the opportunity to further validate the effect of tumor suppressor inactivation on tumor initiation
and early growth (Fig. 5E; Supplementary Fig. S11B and C). The effects of inactivating each
tumor suppressor gene on relative tumor numbers were highly correlated across all three datasets
(Fig. 5F; Supplementary Fig. S11D and E). Several genes including Cdkn2a, Dnmt3a, Kdm6a
and Ncoa6 that initially only increased tumor number also increased overall growth fitness at the
later time point. This observation suggests some link between the cellular changes that enable
normal epithelial cells to break through the constraints of early hyperplastic growth and the
greater fitness in the resulting tumors (Fig. 4F and 5F; Supplementary Fig. S9B).

Tumor suppressor inactivation allows the emergence of rare but very large tumors

Next, we took advantage of the per-tumor resolution of our Tuba-seq data to quantify the
impact of inactivating each gene on the generation of exceptionally large tumors. In addition to
the effects of tumor suppressor gene inactivation on overall tumor growth and tumor initiation,
the development of exceptionally large tumors is suggestive of genotypes that promote or allow
additional alterations to drive aggressive tumor growth. We previously found that one major
effect of p53 deficiency is the generation of such exceptionally large tumors (26,27). Using
metrics such as the Hill’s estimator (a measure of the heavy-tailedness of a distribution)(52), we
quantified the extent to which p53 inactivation enables the emergence of infrequent but
exceptionally large tumors after 15 weeks of tumor growth (Fig. 6A and B; Supplementary Fig.
The effect of p53 inactivation is consistent with many previous reports documenting the emergence of large lung tumors in Kras\textsuperscript{LSL-G12D/\textsl{+};p53\textsuperscript{flox/flox}} mice (32,53-55). These analyses also showed that inactivation of Cdkn2a and the DNA methyltransferase Dnmt3a, might allow some tumors to grow to disproportionately large sizes (Fig. 6A and B; Supplementary Fig. S12A).

To further investigate the effects of tumor suppressor gene inactivation on the emergence of exceptionally large tumors, we determined which genotypes generate heavy-tailed tumor size distribution after 26 weeks of tumor growth. Analysis of the distributions of tumor sizes specifically highlighted the development of exceptionally large Dnmt3a and Cdkn2a-targeted tumors (Fig. 6C-E; Supplementary Fig. S12B-D). Both sgRNAs targeting Cdkn2a are anticipated to inactivate both INK4A and ARF, therefore the effect of Cdkn2a inactivation could reflect the combined reduction of the Rb and p53-pathways, consistent with our observation that p53 inactivation generates a heavy-tailed distribution (Fig. 6A and B; Supplementary Fig. S12A)(26,27). The emergence of very large Cdkn2a- and Dnmt3a-deficient tumors is consistent with the increased lung tumor burden in oncogenic Kras\textsuperscript{LSL-G12D}-driven tumors with Cre/\textsl{lox} mediated inactivation of these genes (56,57). However, the per-tumor resolution of our data suggests that the inactivation of INK4A/ARF or the DNA-methyltransferase DNMT3A enables the emergence of rare but exceptionally large tumors, while having only a modest impact on the growth of the vast majority of tumors (Fig. 6E; Supplementary Fig. S12C). Therefore, the role of tumor suppressors in preventing the development of exceptionally large tumors can be independent of their roles in regulating tumor initiation and overall growth during cancer evolution.

Limited effects of overall tumor burden and sex on tumor suppressor function
Our high-resolution data across multiple facets of tumor suppression in principle allow for quantification of the effects of other variables on tumor suppressor effects. Given that overall tumor burden varies across mice and that we initiated tumors in mice of both sexes, we assessed how these variables influence tumor suppressor effects. To uncover whether overall tumor burden influences genotype-specific effects, we divided our \( KT;H11^{LSL-Cas9} \) mice with Lenti-sgTS102/Cre-initiated tumors into three groups with low, medium, and high tumor burden and reassessed multiple metrics of tumor initiation and growth (Supplementary Fig. S13A). Very few genotype-specific tumor-suppressive effects were influenced by overall tumor burden, suggesting that our results are largely unaffected by potential differences in paracrine or physical interactions that change with tumor density (Supplementary Fig. S13B-E).

There is a growing interest in understanding sex-specific effects on all aspects of carcinogenesis. Our data derived from both male and female mice allowed us to investigate sex-specific differences in tumor suppression. Inactivation of most genes, including those on the X chromosome, had similar effects on tumor growth and tumor number in male and female mice (Supplementary Fig. S14A-D). Thus, tumor suppressor effects in lung cancer are not dramatically impacted by differences in the host environment driven by sex. This was particularly illuminating for \( Kdm6a \), which is an X-linked gene that has both H3K27me3 demethylase and non-enzymatic functions (58). Its non-enzymatic function can be compensated for by its paralog UTY on the Y chromosome, and thus different effects in male and female mice have been used to provide insight into the molecular function of KDM6A (58). \( Kdm6a \) inactivation increased tumor number similarly in male and female mice. The effects were consistent in our data at 15 and 26 weeks after tumor initiation, suggesting that the impact of...
KDM6A inactivation is most likely driven by loss of its enzymatic function (Supplementary Fig. S14E-H).

Evaluation of sensitivity and specificity

To better estimate the impact of false negatives and false positives on our data, we used all of our datasets to estimate the true positive rate (Methods). Within all of our datasets, the effects of sgRNAs targeting the same gene were concordant across multiple metrics, consistent with on-target effects (Fig. 2 and 4; Supplementary Fig. S15A-F). For instance, in our experiment using Lenti-sgTS102/Cre pool, when one sgRNA showed a significant tumor suppressive effect (nominal \( P < 0.05 \)), the probability to re-detect the significant effect using the other guide was above 89% for all metrics assessed (Supplementary Table S3). Thus, the probability that both sgRNAs fail to uncover a functional tumor suppressor that has a similar effect to the tumor suppressors identified in our analysis is below 5% (Supplementary Table S3). Note that for the eight major tumor suppressor genes that were excluded from the Lenti-sgTS85/Cre Pool, significant effects for both sgRNAs were uncovered in every case. Given these results and the targeting of each putative tumor suppressor gene with two sgRNAs, it is unlikely that functional tumor suppressors were missed for technical reasons. Furthermore, analysis of sgRNA cutting in cells in culture showed comparable efficiency of sgRNAs targeting genes that emerged as tumor suppressors and those that did not (Supplementary Fig. S15G-I). Finally, power calculations using our data suggest that an even larger number of genes could be assessed using reasonable numbers of mice using these methods (Supplementary Fig. S16A-C).
Human mutational data, cell line studies, and in vivo functional studies are complementary in defining a catalog of tumor suppression

The candidate tumor suppressor genes that we assessed were chosen based on existing human mutational data; however, each gene has different levels of correlative data supporting its function as a tumor suppressor (Supplementary Table S1). We explored whether effects on tumorigenesis within the autochthonous environment could be predicted by either human mutation data or through the analysis of human cell lines. Several strong functional tumor suppressors did not stand out based on the human mutational frequency data, and genes such as STAG2, CMTR2, and CDKN2C were not often predicted to be tumor suppressor genes based on human mutational data (Fig. 2A; Supplementary Fig. S17A-G). Thus, computational predictions of tumor suppressor function from mutational data alone (including statistical methods that already integrate background mutation rate corrections as well as function- and structure-based impact predictions) nominate some but not all functional tumor suppressors.

Analysis of data from the Dependency Map (59), in which genome-scale knockout screens were performed across diverse cancer cell lines, was also revealing. Inactivation of several top functional tumor suppressors, including PTEN, CDKN2C, RB1, and RNF43 increased lung adenocarcinoma cell line growth as expected (Supplementary Fig. S17H). However, inactivation of several other major functional tumor suppressors, including LKB1, SETD2, and STAG2 paradoxically decreased cancer cell growth in culture (Supplementary Fig. S17H). The effects of inactivating several modest tumor suppressors were concordant between the human cell lines and in vivo mouse model data, although inactivation of some genes, including CMTR2, RBM10, and KEAP1, had variable or growth-suppressive effects on cancer cells in culture (Fig.
DISCUSSION

The enormous genomic diversity in cancer, even within tumors of the same subtype, creates a challenge for identifying driver genes and deciphering their roles in tumor development. Given the sample sizes of cancer genome sequencing studies, variation in genomic features such as gene length and mutation rate will continue to make computational predictions of tumor suppressor function from mutation data difficult, except for a subset of genes (9,60,61). Moreover, mutation frequencies alone cannot easily define the importance of each tumor suppressor gene and even less so be used to glean their mode of action. Indeed, even rarely mutated tumor suppressor genes can have large consequences when inactivated, with the rarity of mutation being driven by mutational cold spots, epistatic interactions and biological context (9,62) rather than by the magnitude of their inhibitory function (Supplementary Fig. S17A).

Thus, while experiments using model organisms could be impacted by species-specific effects, in vivo functional studies that include autochthonous tumor initiation, growth and progression are an important complement to the computational investigation of tumor suppressor inactivation in human tumors (13,20,21).

Carcinogenesis is broadly impacted by different aspects of the in vivo environment. By enhancing the throughput, sensitivity, and precision of Tuba-seq (26,27), we quantify the effects of inactivating a diverse panel of putative tumor suppressor genes in an autochthonous mouse model of oncogenic KRAS-driven lung cancer. The parallel analysis of ~50 different genotypes not only uncovered previously uncharacterized functional tumor suppressor genes but also
provided new insights into the landscape of tumor suppression and multiple modes of action of
tumor suppressor genes (Fig. 7A and B). We show that tumor suppression is unexpectedly
complex and multi-faceted, with some genes suppressing tumor initiation, some constraining
overall tumor growth, and others limiting the emergence of a small proportion of unusually fast-
growing tumors (Fig. 7A and B). Furthermore, while some genes affect only a single feature of
carcinogenesis, others affect multiple facets of tumor evolution to varying extents (Fig. 7C). The
relative importance of these genes can also change during the course of carcinogenesis (Fig. 7B
and C). Understanding the impact of tumor suppressors that primarily regulate certain aspects of
carcinogenesis may have a unique value for cancer prevention, early detection, and therapeutic
targeting. The discovery of such functional complexity points to shifting challenges during
different stages of carcinogenesis. Thus, tumor suppressors are not simply “brakes” on
proliferation but rather contextually and temporally dependent genetic modifiers of different
phases of carcinogenesis.

Our results are largely consistent with previous studies that assessed some of these genes
individually using similar in vivo mouse models of lung cancer (22,26,31-34,51,63,64).
However, single-gene approaches and quantification of overall tumor burden alone are limited in
their ability to uncover the modes of tumor suppression and do not enable direct comparison
across many genotypes. For example, while Lkb1, Pten, Kdm6a, Dnmt3a and p53 inactivation
each increase overall tumor burden, our quantitative, multiplexed design and computational
platform uniquely enabled the deconvolution of different aspects of tumor suppression (Fig. 7A).

We show that the inactivation of many understudied genes has major effects on tumor
growth (Fig. 7C; Supplementary Fig. S3). Identifying additional genes that are fundamentally
important in suppressing carcinogenesis, including those that are less frequently mutated in
human lung adenocarcinoma, can highlight key molecular and cellular processes that are critical in cancer. Furthermore, alterations in cis-regulatory elements, epigenetic silencing and mutations in other members of the same complexes or pathways likely dysregulate these processes in a much higher percentage of tumors. Thus, these types of in vivo findings suggest not only the importance of certain genes but also more broadly uncover under-appreciated cellular processes that limit cancer development. Our findings nominate several novel genes and key pathways that should be investigated in further mechanistic detail. In particular, the mechanisms by which STAG2 inactivation drives lung cancer growth remain to be elucidated.

One key approach used to implicate the context-dependency of tumor suppressor function is the analysis of mutual exclusivity in human data (65). Interestingly, our data demonstrate that genes that trend toward mutual exclusivity with oncogenic KRAS mutations, such as NF1 and PTEN are still important suppressors of oncogenic KRAS-driven lung cancer (Supplementary Fig. S17B). Such statistical trends toward mutual exclusivity should not be misinterpreted as the lack of tumor-suppressive effect of these genes in oncogenic KRAS-driven lung cancer, and more generally, these types of patterns in mutation data should be interpreted with caution (66). Instead, these patterns likely reflect complex epistatic interactions in which context-dependence drives frequencies and mutation spectra (9,62).

Our data, coupled with human lung adenocarcinoma sequencing studies, provide the most comprehensive map of in vivo tumor suppressor gene function for cancer (Fig. 7C). Given the quantitative and cost-effective nature of Tuba-seq, even broader studies of many other genes and combinations of genomic alterations may be warranted. Moreover, studies across different genetic and environmental contexts may further elucidate and refine the modality and context-dependence of tumor suppressor gene effects (27,67,68). This should lead to a more thorough
understanding of the interactions between cell-intrinsic and extrinsic processes that contribute to 
the etiology and evolution of lung cancer.

CONTRIBUTIONS

METHODS

Selection of candidate tumor suppressor genes for this study

To select candidate genes to assess in vivo using Tuba-seq (and to complement genomics and cell biology approaches), we generated a highly human-curated panel that integrating many different considerations.

Known lung adenocarcinoma driver tumor suppressors genes at >5% mutational frequency (such as \emph{P53}, \emph{LKB1}, \emph{CDKN2A}, \emph{KEAP1}) from The Cancer Genome Atlas (TCGA), AACR Project Genomics, Evidence, Neoplasia, Information, Exchange (GENIE), and TRAcking Cancer Evolution through therapy (Rx) (TRACERx) datasets which were previously assessed by
Tuba-seq were included as positive controls. We included genes that tend to co-occur with oncogenic \textit{KRAS} mutations and those that do not. We also included genes that have been categorized as tumor suppressor genes in other cancer types with >5% mutational frequency in lung (such as \textit{KDM6A} and \textit{FAT1}), even if they are not predicted to be involved in lung adenocarcinoma (Fig. 1A; \textbf{Supplementary Fig. S1} and Table S1).

We also considered the distribution of mutations within genes (Fig. 1B), including low mutation frequency genes (<5%) that show potential clonal or subclonal bias from the TRACERx dataset (\textbf{Supplementary Table S1}), genes with discrepancies in scoring of potential driver activity (\textbf{Supplementary Fig. S2}), as well as genes that represent biological processes or functions commonly associated with carcinogenesis (\textbf{Supplementary Fig. S3}). From a curated survey of literature, candidate genes that have been discussed as cancer driver genes without much or any functional data were also included (\textbf{Supplementary Fig. S4}).

\textbf{Analysis of human lung adenocarcinoma cancer genome sequencing data}

Mutation frequencies and other information for the 48-gene panel of putative candidate tumor suppressor genes are available from multiple cancer datasets and their analyses in TRACERx (6), GENIE (2) and TCGA (7,69,70). Oncogenes are characterized by missense point mutations arising in mutational hotspots. In contrast, TSGs are characterized by protein truncating mutations (nonsense and frameshifts) that are more dispersed across the transcript. Moreover, when nonsense and frameshift mutations arise in oncogenes, they tend to truncate C-terminal domains and occur towards the end of the transcript. To identify putative TSGs, we characterized all genes in this survey by these two genetic features: mutational hotspots and the fraction of protein truncated per mutation. We used all point mutations and short insertion and
deletions found within the TCGA lung adenocarcinoma (7) and Catalogue Of Somatic Mutations In Cancer (COSMIC)(71) databases. The extent of mutational hotspots within a gene was determined using a normalized measure of dispersion (Green’s Contagion) of the number of missense mutations observed within all five residue rolling windows in each gene:

\[(\sigma^2/\mu-1)/(\mu N-1)\]

where \(\mu\) is the mean number of missense mutations observed within each window, \(\sigma^2\) is the unbiased estimator of the variance, and \(N\) is the number of missense mutations. Green’s Contagion and the five-residue window size and were chosen because they maximized the accuracy of classification of known oncogenes and tumor suppressors. Larger values of Green’s Contagion suggest that mutations are clumping at a few residues within the protein and that the mutant gene is likely oncogenic. This measure has a value of zero when mutations are randomly dispersed throughout the gene and can be negative when mutations are under-dispersed. The fraction of protein truncated per mutation is the mean number of amino acids lost per nonsynonymous mutation. It is calculated by simply averaging the fraction of a transcript lost due to each frameshift and nonsense mutation, while assigning a value of zero to all missense mutations in this collective average.

To summarize what has previously been described about the biological functions of the candidate genes, we used driver gene scores from attempts to discover cancer driver genes using multiple approaches, such as weighted consensus across multiple tools (8) and prediction by machine learning (29). We also collated the known biological processes and subcellular localization of the 48 genes from the Gene Ontology database (release date 2019-07-01)(30).

For co-occurrence of mutations in KRAS and each selected gene, the odds ratio (equals

\[\frac{N_{\text{neither were mutated}} \times N_{\text{both were mutated}}}{N_{\text{only KRAS is mutated}} \times N_{\text{only selected gene is mutated}}}\]

and P-value (one-sided Fisher’s Exact Test) were available on cBioPortal.org. 566 lung adenocarcinoma
cases from TCGA Pan-cancer Atlas and 8522 lung adenocarcinoma samples from GENIE were
analyzed. Note that NCOA6, ATF7IP, CMTR2 and UBR5 are not profiled in any GENIE lung
adenocarcinoma cases and hence were excluded from the analysis. For the fitting of a simple
linear regression between measured phenotypes and observed clinical parameters, we used data
from mutation timing and clonality in lung adenocarcinomas that have been previously described
(6,70).

Analysis of publications suggesting tumor suppressive function of each putative tumor
suppressor gene in lung cancer

List of articles related to the gene was accessed through the “Bibliography” section of
suppressor” were used as the keywords to refine the search.

Calculation of gene inclusion in gene sequencing panels

GENIE panel sequencing information was compiled through the GENIE 6.1 Public
Release. We first generated a list of panels that provided data from patients with “Cancer Type
Detailed” listed as “Lung Adenocarcinoma”, “Lung Adenocarcinoma In Situ”, or “Lung
Adenosquamous Carcinoma” by filtering the data_clinical_sample.txt file. Then, by parsing the
genie_combined.bed file, we generated a list of “screened” genes for each panel, which refers to
genes that have “Feature_Type” listed as “exon” and “includeInPanel” listed as “True”. This list
was then utilized to categorize our pool of tumor suppressors as either “screened” or
“unscreened” by these sequencing panels. Stanford Solid Tumor Actionable Mutation Panel
(STAMP) and FoundationOne CDx sequencing panels were obtained from the official websites.
Design, generation, barcoding, and production of lentiviral vectors

The sgRNA sequences targeting the putative tumor suppressor genes were designed using Desktop Genetic’s Guide Picker (72) (https://www.deskgen.com/guide-picker) to prioritize on-target activity (score of >0.6)(73), specificity (score of >0.6)(74), likelihood of generating frameshift indels (score of >0.6)(75), targeting of maximal number of transcript isoforms, no homopolymer runs in the sgRNA, and no extremes in GC-content of sgRNA (0.4-0.75), as detailed in Supplementary Table S2.

The Lenti-U6-sgRNA-sgID-barcode-Pgk-Cre vector was modified from our previous work (26) as follows. The sgRNA sequence of the previously described pLenti-sgNT1/Cre (Addgene #66895) vector was replaced with GCGAGGTATTACCGGCGTATCATCCGCG by site-directed mutagenesis to generate pLenti-BaeI-Pgk-Cre. The replacement sequence contains a recognition site for the Type IIS restriction endonuclease BaeI, allowing for quick replacement of the sgRNA sequence. To generate each desired vector, forward and reverse single-stranded oligonucleotides containing the sgRNA sequence and complementary overhangs is annealed and ligated into the BaeI-linearised pLenti-BaeI-Pgk-Cre vector using T4 DNA ligase. The barcode oligo primer contains the 8-nucleotide sgID sequence and 20-nucleotide degenerate barcode (Supplementary Table S2). The generation of the barcode fragment and subsequent ligation into the vectors were performed as previously described (26).

Lenti-sgRNA/Cre vectors were individually co-transfected into 293T cells with pCMV-VSV-G (Addgene #8454) envelope plasmid and pCMV-dR8.2 dvpr (Addgene #8455) packaging plasmid using polyethylenimine. Supernatants were collected at 48 and 72 hours after transfection, filtered through a 0.45 µm syringe filter unit (Millipore SLHP033RB) to remove
cells and debris, concentrated by ultracentrifugation (25,000 g for 1.5 hours at 4°C), and
resuspended in PBS. Each virus was titered against a standard of known titer using LSL-YFP
Mouse Embryonic Fibroblasts (MEFs) (a gift from Dr. Alejandro Sweet-Cordero/UCSF). These
MEFs and 293T cells were regularly tested with MycoAlert mycoplasma detection kit (Lonza,
cat# LT07-418) to make sure that they are free of mycoplasma. All lentiviral vector aliquots
were stored at -80°C and were thawed and pooled at equal ratios immediately prior to delivery to
mice.

Mice and tumor initiation

The use of mice for the current study has been approved by Institutional Animal Care and
Use Committee at Stanford University, protocol number 26696.

Kras<sup>LSL-G12D/+</sup> (RRID:IMSR_JAX:008179), R26<sup>LSL-tdtomato</sup> (RRID:IMSR_JAX:007909),
and H11<sup>LSL-Cas9</sup> (RRID:IMSR_JAX:027632) mice have been previously described (24,76,77).
They were on a C57BL/6:129 mixed background. The Stag2<sup>2<sup>tm1c(EUCOMM)Wtsi</sup>/J</sup> (Stag2<sup>fox</sup>) mice
were initially generated by Viny et al. (42) and obtained from the Jackson Laboratory
(RRID:IMSR_JAX:030902). Tumors were initiated by intratracheal delivery of 60 µl of
lentiviral vectors dissolved in PBS.

For the initial experiments, tumors were allowed to develop for 15 weeks after viral
delivery of a lentiviral pool that contained 102 barcoded Lenti-sgRNA/Cre vectors (Lenti-
sgTS102/Cre). Tumors were initiated in Kras<sup>LSL-G12D,R26LSL-Tom/LSL-Tom</sup> (KT) mice with 9x10<sup>4</sup>
infected units (ifu)/mouse of the Lenti-sgTS102/Cre pool (12 mice analyzed at 15 weeks after
tumor initiation), and in KT;H11<sup>LSL-Cas9/LSL-Cas9</sup> mice with 3x10<sup>4</sup> ifu/mouse of the Lenti-
sgTS102/Cre pool (47 mice analyzed at 15 weeks after tumor initiation).
After the detection of the top functional tumor suppressors after 15 weeks of tumor development, tumors were initiated in additional mice using a sub-pool of 85 Lenti-sgRNA/Cre vectors (Lenti-sgTS85/Cre), which excluded the vectors targeting Cdkn2c, Lkb1, Nf1, p53, Pten, Rb1, Setd2, and Stag2. Tumors were initiated in KT mice with 2.5x10^5 ifu/mouse (6 mice analyzed at 15 weeks after tumor initiation), KT;H11^LSL-Cas9 mice with 6x10^4 ifu/mouse (10 mice analyzed at 15 weeks after tumor initiation), and KT;H11^LSL-Cas9 mice with 1.5x10^4 ifu/mouse (40 mice analyzed at 26 weeks after tumor initiation).

For the validation experiments using Lenti-sgRNA/Cre-mediated gene inactivation, tumors were allowed to develop for 15 weeks after viral delivery. Tumors were initiated with individual barcoded Lenti-sgRNA/Cre vectors in KT mice with 1x10^5 ifu/mouse (3 mice per vector analyzed at 15 weeks after tumor initiation), and KT;H11^LSL-Cas9 mice with 1x10^5 ifu/mouse (5-6 mice per vector analyzed at 15 weeks after tumor initiation).

For the survival experiments using Lenti-sgRNA/Cre-mediated gene inactivation, tumors were allowed to develop until humane endpoints. Tumors were initiated in KT;H11^LSL-Cas9 mice with individual barcoded Lenti-sgInert/Cre vectors at 2x10^4 ifu/mouse and with individual barcoded Lenti-sgStag2/Cre vectors at 1x10^4 ifu/mouse (7 mice per vector analyzed).

For Stag2 validation experiments using the Stag2^floxed allele, tumors were initiated with Lenti-sgInert/Cre in KT, KT;Stag2^floxed, KT;Stag2^floxed and KT;Stag2^floxed mice with 1x10^5 ifu/mouse (4-5 mice per group analyzed) and allowed to develop for 15 weeks, and KT, KT;Stag2^floxed, KT;Stag2^floxed and KT;Stag2^floxed mice with 1x10^5 ifu/mouse (6-7 mice per genotype analyzed) and allowed to develop until humane endpoints.

**Tuba-seq library generation**
Genomic DNA was isolated from bulk tumor-bearing lung tissue from each mouse as previously described (26). Briefly, benchmark control cell lines were generated from LSL-YFP MEFs transduced by a barcoded Lenti-sgNT3/Cre vector (NT3: an inert sgRNA with a distinct sgID) and purified by sorting YFP+ cells. For mice initiated with Lenti-sgTS102/Cre pool, twelve benchmark control cell lines (3 cell lines of 500,000 cells each, 3 cell lines of 50,000 cells, 3 cell lines of 5,000 cells, and 3 cell lines of 500 cells) were added to each mouse lung sample prior to lysis to enable the calculation of the absolute number of neoplastic cells in each tumor from the number of sgID-BC reads. Because the standard curve was highly linear, we reduced the benchmark controls to three cell lines with 500,000 cells each for the Lenti-sgTS85/Cre pool. Following homogenization and overnight protease K digestion, genomic DNA was extracted from the lung lysates using standard phenol-chloroform and ethanol precipitation methods.

Subsequently, Q5 High-Fidelity 2x Master Mix (New England Biolabs, M0494X) was used to amplify the sgID-BC region from 32 µg of genomic DNA. The unique dual-indexed primers used were Forward: AATGATACGGCGACCACCGAGATCTACAC-8 nucleotides for i5 index-ACACTCTTTCCCTACACGACGCTCTTCCGATCT-6 to 9 random nucleotides for increased diversity-GCGCACGTCTGCCGCGCTG and Reverse: CAAGCAGAAGACGGCATACGAGAT-6 nucleotides for i7 index-GTGACTGGAGTTCAGACGTGTGCTCTTCCGATCT-9 to 6 random nucleotides for increased diversity-CAGGTTCTTGCGAACCTCAT. The PCR products were purified with Agencourt AMPure XP beads (Beckman Coulter, A63881) using a double size selection protocol. The concentration and quality of the purified libraries were determined using Agilent High Sensitivity DNA kit (Agilent Technologies, 5067-4626) on the Agilent 2100 Bioanalyzer (Agilent Technologies, G2939BA). The libraries were pooled based on lung weight to ensure
even reading depth, cleaned up again using AMPure XP beads, and sequenced (read length 2x150bp) on the Illumina HiSeq 2500 or NextSeq 550 platform (Admera Health Biopharma Services).

Code and data availability

Python 3.6 and R 3.6 were used for analyzing the data. The codes are available on GitHub, link: https://github.com/lichuan199010/functional-taxonomy-of-tumor-suppressors

The data sets generated and analyzed in the current study are available in the NCBI Gene Expression Omnibus database, token: ezsjeksixhkvqh, link: https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE146302

Process paired-end reads to identify the sgID and barcode

The FASTQ files were parsed to identify the sgID and barcode for each read. Each read is expected to contain an 8-nucleotide sgID region followed by a random nucleotide barcode region (GCNNNNNTANNNNGC), and each of the 20 Ns represents random nucleotides. The sgID region identifies the putative tumor suppressor gene being targeted, for which we require a perfect match between the sequence in the forward read and one of the 102 sgIDs with known sequences. Note that all sgID sequences differ from each other by at least three nucleotides. Therefore, the incorrect assignment of sgID due to PCR or sequencing error is extremely unlikely. All cells in a clonal expansion from a cell transduced by a lentiviral vector carry the same BC sequence. To minimize the effects of sequencing errors on calling the BC, we require the forward and reverse reads to agree completely within the random nucleotide sequence to be further processed. In our pipeline, any “tumor” within a Hamming distance of
two from a larger tumor is assigned as “spurious tumors”, which is likely to be resulting from sequencing or PCR errors and is removed from subsequent analysis. Reads with the same sgID and barcode are assigned to be the same tumor. The tumor size (number of neoplastic cells) is calculated by normalizing the number of reads from an individual tumor to the number of reads from the benchmark control cell lines added to each sample prior to lung lysis and DNA extraction. The minimum sequencing depth was ~1 read per 43 cells. We have high statistical power in identifying tumors with over 200 cells, which was used as the minimum cell number cutoff for calling tumors.

**Summary statistics for overall growth rate**

Three summary statistics, relative sizes at defined percentiles, relative log-normal mean and relative tumor burden (will be introduced in a later section), were used to describe the overall tumor growth as previously described. Relative sizes at defined percentiles are nonparametric summary statistics for the tumor size distribution. Specifically, the relative sizes at Xth percentiles are calculated as the Xth percentile (X represents 50% (median), 60%, 70%, 80%, 90% and 95%) of the tumor size distribution of sgTS tumors divided by the corresponding percentile of the tumor size distribution of all sgInert tumors. This ratio represents the growth advantage at various percentiles conferred by the inactivation of the tumor suppressor gene.

\[
\text{Relative size of tumors at } X^{\text{th}} \text{ percentile} = \frac{\text{Neoplastic cell number at the } X^{\text{th}} \text{ percentile for sgTS tumors}}{\text{Neoplastic cell number at the } X^{\text{th}} \text{ percentile for sgInert tumors}}
\]

Log-normal mean is the maximum likelihood estimator for the mean number of neoplastic cells for sgTS tumors assuming a log-normal distribution of tumor sizes. Similarly, we
calculate the relative log-normal mean by dividing the log-normal mean of sgTS tumors by the log-normal mean of the sgInert tumors (Supplementary Fig. S4).

Relative log – normal mean = \frac{\text{log normal mean for sgTS tumors}}{\text{log normal mean for sgInert tumors}}

Summary statistics for heavy-tailedness of the tumor size distribution

Some tumor suppressor genes may lead to rare cases of exceptionally large tumors, which results in a tumor size distribution with a heavy tail. We used two summary statistics, relative Hill’s estimator and relative steepness to characterize the heavy-tailedness of the tumor size distribution.

Hill’s estimator is a commonly used tail index to characterizes the tail shape of heavy-tailed distributions (52). Suppose \(X_1, X_2, \ldots, X_n\) are sgTS tumor sizes, and we order them by size such that \(X_1 \geq X_2 \geq \ldots \geq X_n\). Let \(X_k\) be the tumor size at the 95\(^{th}\) percentile, and the Hill’s estimator is calculated as,

\[ H = \frac{1}{k} \sum_{i=0}^{k} \ln \left( \frac{X_i}{X_k} \right) \]

The relative Hill’s estimator is calculated by dividing the Hill’s estimator for tumors with sgTS by that of tumors with sgInert.

Relative Hill’s estimator = \frac{H \text{ for sgTS tumors}}{H \text{ for sgInert tumors}}

The steepness (99\(^{th}\) percentile / 95\(^{th}\) percentile) is calculated as the ratio of the 99\(^{th}\) percentile over the 95\(^{th}\) percentile for the tumor size distribution for each sgID. Large values of these estimators indicate that the tumor size distributions are heavy-tailed. We calculate the relative steepness by dividing the steepness of tumors with sgTS by that of tumors with sgInert.
Steepness = \frac{\text{Number of neoplastic cells at the 99}\text{th percentile for } \text{sgTS tumors}}{\text{Number of neoplastic cells at the 95}\text{th percentile for } \text{sgInert tumors}}

Relative steepness = \frac{\text{Steepness for } \text{sgTS tumors}}{\text{Steepness for } \text{sgInert tumors}}

For both relative Hill’s estimator and relative steepness, values higher than one indicate that the gene inactivation leads to heavier tail and value smaller than one indicate gene inactivation leads to lighter tail than expected (Supplementary Fig. S4).

Summary statistics for relative tumor number and relative tumor burden

The four metrics above compare the tumor size distribution of sgTS tumors relative to sgInert tumors and can be calculated for both KT;H11LSL-Cas9 mice and KT mice, separately. Unlike these size metrics, relative tumor number and relative tumor burden are affected linearly by lentiviral titer. Therefore, when calculating these two metrics, we normalized it to that that in KT mice to account for the viral titer differences among different Lenti-sgRNA/Cre vectors.

We normalized the observed tumor number for sgTS tumors in KT;H11LSL-Cas9 mice by dividing it by that of sgTS tumors in KT mice to account for the titer differences for each sgTS.

\[ \text{Tumor number} = \frac{\sum_{\text{tumor number in KT;H11LSL-Cas9 mice}}}{\sum_{\text{tumor number in KT mice}}} \text{for each sgTS} \]

The relative tumor number is calculated as the ratio of tumor number for each sgTS relative to sgInert:

\[ \text{Relative tumor number} = \frac{\text{Tumor number for } \text{sgTS tumors}}{\text{Tumor number for } \text{sgInert tumors}} \]

The relative tumor number is a metric that reflects the probability of tumor initiation. If the tumor suppressor genes normally constrain tumor initiation, inactivation of the gene will increase the relative tumor number to be larger than 1.
Similarly, we normalized the observed tumor burden for sgTS tumors in KT;H11LSL-Cas9 mice by dividing it by that of sgTS tumors. The relative tumor burden is calculated as the ratio of the tumor burden for each sgTS relative to sgInert:

$\text{Tumor burden} = \frac{\sum \text{neoplastic cell number in } KT; H11^{LSL-Cas9} \text{ mice}}{\sum \text{neoplastic cell number in } KT \text{ mice}}$ for each sgTS

$\text{Relative tumor burden} = \frac{\text{Tumor burden for sgTS tumors}}{\text{Tumor burden for sgInert tumors}}$

The relative tumor burden is determined mostly by the largest tumors. For instance, the top 1% of tumor cells accounts for over 50% of total tumor burden in KT;H11LSL-Cas9 mice at 11 weeks. Both TS inactivation that leads to faster overall growth, rare but exceptionally large tumors and tumor initiation rate will result in an increase in relative tumor burden (Supplementary Fig. S4).

**Bootstrapping the tumors**

In the calculation of confidence intervals and $P$-values, we needed to generate distributions of the statistic considering both variation of tumor sizes across mice and within the same mice. We adopted a two-step bootstrap resampling process. We first bootstrap resampled mice to generate a pseudogroup of mice and then within each group of resampled mice, we bootstrap resampled all observed tumors carrying each sgID.

**Calculation of confidence intervals and $P$-values for size metrics**

We have four size metrics that describe the overall growth (relative log-normal mean, relative percentiles) and the heavy tailedness (relative Hill’s estimator and relative steepness) of the tumor size distribution. For each of these metrics, we bootstrapped tumors 10,000 times and
calculate 10,000 values of each statistic for these bootstrap resampling. The 95% confidence interval is calculated as the 2.5\textsuperscript{th} percentile and the 97.5\textsuperscript{th} percentile of these bootstrapped results, while the $P$-value is calculated as the proportion of bootstrapped results that are not in the same direction as the observed score compared with the baseline of 1.

**Calculation of $P$-values for tumor burden and tumor number**

We bootstrap tumors in both the $KT;H11^{LSL-Cas9}$ and $KT$ mice and calculate the relative tumor burden and relative tumor number from these bootstrapped mice. The process was repeated $10^6$ times. The 95\% confidence interval is calculated as the 2.5\textsuperscript{th} percentile and the 97.5\textsuperscript{th} percentile of these bootstrapped results, while the $P$-value is calculated as the proportion of bootstrapped values that are not in the same direction as the observed score compared with the baseline of 1.

**Robustness to tumor burden differences**

To investigate whether overall tumor burden has an impact on genotype-specific tumor initiation and growth, we calculated summary statistics for tumor initiation and tumor size distribution on groups of mice with different overall tumor burden. Specifically, we divided the 47 $KT;H11^{LSL-Cas9}$ mice with Lenti-sgTSI02/Cre-initiated tumors at the 15-week time point into three groups based on the total tumor burden in each mouse, namely the low tumor burden group (16 mice), the medium tumor burden group (16 mice), and the high tumor burden group (15 mice). We performed calculations separately for each group for four metrics (95\textsuperscript{th} percentile tumor size, log-normal mean, tumor burden, and tumor number) and evaluated whether these metrics show any correlation with tumor burden.
Quantification of sex differences

For each statistic, we use the ratio to quantify the differences between female mice and male mice. The ratio is calculated as,

\[
\text{Ratio} = \frac{X_{\text{Female}}}{X_{\text{Male}}}
\]

Where \(X_{\text{Male}}\) and \(X_{\text{Female}}\) are the statistics quantified in male and female mice, respectively. When calculating the \(P\)-values, we respectively bootstrapped tumors in male and female mice and calculated the proportion of times that the bootstrapped results are not in the same direction as the observed score compared with the baseline of 1.

Empirical estimation of true positive rates

We estimated the power (true positive rate) for each of the three experiments, (1) Lenti-sgTS102/Cre; 15-week experiment, (2) Lenti-sgTS85/Cre; 15-week experiment, and (3) Lenti-sgTS85/Cre; 26-week experiment. Understanding the true positive rate is important for understanding the probability of identifying functional tumor suppressor genes. Since we do not have a list for genuine functional tumor suppressor genes, we used each sgRNA that generated a significant tumor suppressor effect (with nominal \(P < 0.05\)) as a proxy for true tumor suppressor effects.

For each experiment, whenever we detected a significant effect for an sgRNA, we queried whether the other sgRNA targeting that same gene also generated a significant tumor suppressive effect. If the other sgRNA shows significant tumor suppressor effect, then the test is counted as TRUE (\(T\)). If the second sgRNA fails to show a significant tumor suppressor effect, then the test is FALSE (\(F\)). Across all sgRNA (including sgRNA#1 and sgRNA#2 for each
gene), we tallied the number of TRUE and FALSE discoveries. We used additive smoothing by adding a pseudocount of 0.5 to both $T$ and $F$ counts to avoid the zero-probability problem in some cases. Therefore, the estimated false negative rate for a gene targeted with a single sgRNA would be:

$$p = \frac{F + 0.5}{(T + 0.5) + (F + 0.5)}$$

The estimated true positive rate in our experiment is the probability of failing to identify a functional tumor suppressor gene with both of two sgRNAs. Thus, this is:

$$\text{False negative rate} = p^2$$
$$\text{True positive rate} = 1 - \text{False negative rate} = 1 - p^2$$

We performed this calculation separately for four metrics: 95th percentile, log-normal mean, tumor burden, and tumor number. We did not estimate the true positive rate for Hill’s estimator because the number of positive findings was too few for robust estimations.

**In vitro analysis of sgRNA efficiency**

To analyze the relative cutting efficiencies of the sgRNAs, we measured the insertion and deletion (indel) rates at the target sites in $Rosa26^{LSL-Tomato};H11^{LSL-Cas9}$ MEFs that were generated from E12.5 embryos. These MEFs tested negative for mycoplasma contamination using the MycoAlert mycoplasma detection kit (Lonza, cat# LT07-418). $10^5$ MEFs were transduced individually with each Lenti-sgTS/Cre vector and cultured for 1 week followed by FACS-based isolation of Tomato-positive transduced cells. Genomic DNA was extracted from sorted cells using the QIAamp DNA Micro Kit (Qiagen 56304) and subjected to PCR-based target enrichment. Two rounds of PCR were performed with Q5 Master Mix (NEB #M0494L). The first round amplified each of the 97 sgRNA targeted regions (see Supplementary Table S2 for
target-enrichment primer sequences). The second round added unique dual indexed Illumina sequencing adaptors to the amplicons.

These libraries were sequenced on an Illumina NextSeq 500 in the 2x150 base-pair paired-ended configuration (Admera Health Biopharma Services). The resulting reads were demultiplexed based on their sample indexes. CRISPRessoPooled was used to quantify on-target indel mutations (78). Briefly, pooled reads were initially demultiplexed into files according to their specific sgRNA and aligned to the reference sequence to identify indel mutations. Substitution events were ignored and all indels that occurred within 10 nucleotides of the predicted target site (3 nucleotides upstream from the NGG PAM) were counted as on-target indel mutations. Indel percent mutated was calculated as the number of reads with an on-target indel divided by the total number of reads.

**Histology and immunohistochemistry (IHC)**

Lung lobes were inflated with PBS/4% paraformaldehyde and fixed for 24 hours, stored in 70% ethanol, and paraffin-embedded and sectioned. 4 μm thick sections were used for Hematoxylin and Eosin (H&E) staining and immunohistochemistry. Primary antibodies used for IHC were anti-STAG2 (1:500, LifeSpan Cat# LS-B11284, RRID:AB_2725802), anti-NKX2.1 (1: 250, Abcam Cat# ab76013, RRID:AB_1310784), anti-Phospho-RPA2 (1:400, Abcam Cat# ab87277, RRID:AB_1952482), anti-Phospho-Histone H2A.X (1:400, Cell Signaling Technology Cat# 9718, RRID:AB_2118009) and anti-Phospho-ERK1/2 (1:400, Cell Signaling Technology Cat# 4370, RRID:AB_2315112). IHC was performed using Avidin/Biotin Blocking Kit (Vector Laboratories, SP-2001), Avidin-Biotin Complex kit (Vector Laboratories, PK-4001) and DAB Peroxidase Substrate Kit (Vector...
Laboratories, SK-4100) following the standard protocols. Human lung adenocarcinoma tissue microarrays were purchased from US Biomax (HLugA120PG01, BC041115e, LC1261, LC706a, NSC155 and NSC157).

Whole Genome Sequencing and quantitative RT-PCR

For whole genome sequencing and qRT-PCR based gene expression analysis, samples were generated from Lenti-Cre initiated tumors from three KT and three KT;Stag2\textsuperscript{flx/flx} mice (a subset of samples from Fig. 3G). Briefly, neoplastic cells were isolated from pooled tumors within two lung lobes of each mouse by FACS for Tomato\textsuperscript{positive} Lineage (CD45/CD31/F4-80/Ter119)\textsuperscript{negative} cells (79). 60,000-100,000 neoplastic cells were collected from each mouse. Genomic DNA and total RNA were purified using Qiagen AllPrep DNA/RNA Micro Kit (Cat# 80284). Genomic DNA was processed with Nextera Flex for karyotyping by low-pass (0.1x coverage) whole genome sequencing. Log\textsubscript{2} ratio of reads mapping to each genomic locus versus the average number of reads mapping to all other comparable loci was plotted.

For qRT-PCR total RNA was reverse-transcribed using Reliance Select cDNA Synthesis Kit with oligo(dT) primers (BioRad Cat# 12012802). Quantitative PCR was performed with PowerUp SYBR Green Master Mix (Thermo Fisher Scientific Cat# A25776) on an Applied Biosystems QuantStudio 3 Real-Time PCR System. PCR primers were:

- **Fos**: 5’-TACTACCATTCCCCAGCCCA-3’ and 5’-GCTGTCACCGTGATGGATGAT-3’;
- **Klf2**: 5’-GAGCCTATCTTGCGATCTT-3’ and 5’-TTGTTTAGGTCCCTGCATCCTGTG-3’;
- **Ifnl3**: 5’-GTGCAGTTCCCACCTCATC-3’ and 5’-TGGGAGTGAATGTGGCTCAG-3’;
- **Ifnb1**: 5’-GTCCTCAACTGCTCTCCACT-3’ and 5’-CATCCAGGGCTAGCCTGTTGTA-3’;
- **Mx1**: 5’-ACGCTGCAGACATACCAGAA-3’ and 5’-CTGTCTCCCTCTGATACGGT-3’;
Ifi44: 5’-ATGGCAGCAAGAAAAGTGCC-3’ and 5’-AAACTTCTGCACACTCGCCT-3’;

Irf1: 5’-CCAGAGATTGACAGCCCTCG-3’ and 5’-TGCACAAGGAATGGCCTGAA-3’;

Gapdh: 5’-TGTGAACGGATTTGGCCGTA-3’ and 5’-ACTGTGCCGTTGAATTTGCC-3’;

Actb: 5’-GGCTCCTAGCACCATGAAGA-3’ and 5’-GTGTAACGCGACTCAGTAACA-3’.

Power analyses

Power analyses were used to evaluate the ability of the Tuba-seq platform to identify functional tumor suppressors across a variety of experimental scenarios. The likelihood of detecting a tumor suppressor depends on the strength of its effect, the number of mice assayed, and the number of guides in the viral pool. We explored how these parameters influence statistical power to detect genes affecting tumor growth and initiation through a pair of non-parametric nested resampling approaches.

For each simulation that focused on tumor growth, a pseudo-cohort of mice (n = 5, 10, 20, 50, 100, 200) was sampled with replacement from the cohort of 47 KT;H1 LSL-Cas9 mice analyzed 15 weeks after tumor initiation, and statistical significance was assessed by bootstrap resampling of tumors from the pseudo-cohort. For a given viral titer, a larger number of multiplexed vectors results in fewer tumors with each sgRNA and a resulting loss of power due to less thorough sampling of the underlying distribution of tumor sizes. To model this effect, the number of tumors sampled from each mouse was scaled by the ratio of the number of sgIDs in the underlying data to the simulated number of sgIDs (n = 10, 20, 50, 100, 200, 500). To capture differences in power due to effect size, we performed analyses for representative strong, moderate, and weak tumor suppressor-targeting sgRNAs (sgNf1#1, sgRb1#1, and sgDot1l#1, respectively). 500 simulations were performed for each gene, with a minimum of 16,000
bootstrap samplings per simulation. In each bootstrap, the size of tumor at the 95\textsuperscript{th} percentile with the focal genotype was compared to the size of tumor with sg\textit{Inert} at the 95\textsuperscript{th} percentile, and significance in each simulation was assessed by bootstrapped $P$-value <0.05 (two-tailed test, Bonferroni-corrected for the simulated number of pooled sgRNAs).

Effects on tumor initiation are inferred through changes in the representation of tumor genotypes in $KT;H1I^{LSL-Cas9}$ mice relative to the original proportions of the sgRNAs in the lentiviral vector pool. As a result, identifying genes that influence tumor initiation requires comparison of $KT;H1I^{LSL-Cas9}$ mice to $KT$ mice, where the relative abundance of genotypes reflects the make-up of the viral pool. For each simulation, we therefore sampled a cohort of both $KT;H1I^{LSL-Cas9}$ and $KT$ mice (n = 5, 10, 20, 50, 100, 200). For simplicity, we maintained the approximate 4:1 ratio of $KT;H1I^{LSL-Cas9}:KT$ used in this study, while ensuring that there was more than 1 $KT$ mouse per cohort (e.g. for 50 total mice we sampled 40 $KT;H1I^{LSL-Cas9}$ and 10 $KT$ mice). Analogous to the tumor size simulations, we model the effect of the number of pooled sgRNAs by scaling the number of tumors sampled from each mouse by the ratio of the number of sgIDs in the underlying data to the simulated number of sgIDs (n = 10, 20, 50, 100, 200, 500); the resulting dataset was then bootstrapped to assess significance. To capture differences in power due to effect size, analyses were performed for representative strong, moderate, and weak suppressors of tumor initiation (sg\textit{Pten}\#2, sg\textit{Kdm6a}\#2, and sg\textit{Ncoa6}\#1, respectively). 500 simulations were performed for each gene, with a minimum of 16,000 bootstrap samplings per simulation. In each bootstrap, the relative tumor number (ratio of number of tumors with focal genotype to number of sg\textit{Inert} tumors) in $KT;H1I^{LSL-Cas9}$ mice was compared to the relative tumor number in $KT$ mice, and significance in each simulation was assessed by bootstrapped $P$-value <0.05 (two-tailed test, Bonferroni-corrected for the simulated number of pooled sgRNAs).
DepMap data and filtering

Cancer cell line dependency data (DepMap Public 19Q4) and mutation data (CCLE) were acquired from the Broad Institute DepMap Portal (RRID:SCR_017655)(59). Lung adenocarcinoma cell lines were identified by their Project Achilles identification code. For each gene of interest, the cell lines that contained damaging mutations within the gene were identified and flagged. Damaging mutations were defined as mutations that likely caused loss of gene function. Subsequently, dependency scores for each gene of interest were exported from both the complete dataset of lung adenocarcinoma cell lines and dataset of cell lines that contains no damaging mutation in the gene of interest. Finally, the distribution of dependency scores across each gene of interest was plotted using GraphPad Prism 8.

FIGURE LEGENDS

Figure 1. An in vivo screen for tumor suppressor genes in autochthonous oncogenic Kras-driven lung tumors.

(A) Candidate tumor suppressor genes were chosen based on multiple criteria including their frequency and known/predicted biological functions. The plot shows the mutation frequencies of these 48 genes across pan-cancer and in lung adenocarcinoma (data from TCGA). Color denotes lung adenocarcinoma driver consensus score derived from multiple prediction tools. Several genes that are mutated at high frequency in lung adenocarcinoma or pan-cancer are labeled.

(B) Features of the mutations in each gene are consistent with tumor suppressor function. Green’s contagion is a measure of mutational hotspots, which characterize oncogenes. Larger values indicate that mutations are enriched in particular residues of the protein. This measure of overdispersion is normalized to not scale with sample size and to be zero when mutations are randomly scattered across the transcript. Average fraction of protein lost by mutation combines the nonsense/frameshift mutation rate and location of the mutations in each gene [(percent of protein transcript altering mutations that are nonsense or frameshift) * (Average fraction of protein lost by nonsense or frameshift mutations)].

(C) Schematic of tumor initiation with our pool of 102 barcoded Lenti-sgRNA/Cre vectors (Lenti-sgTS102/Cre). Each gene is targeted with two sgRNAs, except p53 which is targeted by three sgRNAs. 5 Inert sgRNAs are either non-targeting (NT) or have an active targeting but inert sgRNAs (which target NeoR in the R26<sup>LSL-Tomato</sup> allele). Barcoded Lentiviral vectors contain an sgRNA, Cre, and a 2-component barcode that includes an sgRNA identifier (sgID) and random barcode (BC). This allows inactivation of multiple target genes in parallel followed by quantification of the number of neoplastic cells by high-throughput sgID-BC sequencing. Mouse
genotype, mouse number, and titer of lentiviral vectors are indicated. Tuba-seq was performed on each tumor-bearing lung 15 weeks after initiation, followed by analyses to quantify the indicated metrics. ifu, infectious units.

(D) Fluorescence images of lungs from representative mice at 15 weeks after tumor initiation. Lung lobes are outlined with a dashed white line. Scale bars = 2 mm.

(E) Pearson correlation coefficient ($r$) and $P$-value (two-tailed) suggest strong correlation between neoplastic cell number (an indicator of tumor burden) and lung weight. Each dot represents a mouse. When taking into account that tumors were initiated in $KT;H11^{LSL-Cas9}$ mice with 3-fold less Lenti-sgTS102/Cre vectors, the total neoplastic cell number is ~10-fold greater in $KT;H11^{LSL-Cas9}$ mice than in $KT$ mice.

(F) Volcano plot of the impact of inactivating each putative tumor suppressor gene on relative tumor burden. Each dot represents an sgRNA. Inert sgRNAs are in gray. Tumor suppressor genes are colored pink when both sgRNAs trigger moderate but significant increase and green when one sgRNA triggers >4 fold increase and the other triggers moderate but significant increase. Data is aggregated from 47 $KT;H11^{LSL-Cas9}$ and 12 $KT$ mice.

Figure 2. In vivo lung tumor growth is suppressed by diverse tumor suppressor genes.

(A) The 95$^{th}$ percentile tumor size (normalized to tumors with sg$\text{Inerts}$) for each putative tumor suppressor targeting sgRNA in $KT;H11^{LSL-Cas9}$ mice. Error bars indicate 95% confidence intervals. 95% confidence intervals and $P$-values were calculated by bootstrap. sgRNAs that significantly increase or decrease tumor size are colored as indicated. sg$\text{Inerts}$ are in gray and the dotted line indicates no effect. Genes are ordered based on the average of the 95$^{th}$ percentile tumor sizes from
all sgRNAs targeting that gene, individual sgRNAs targeting each gene were ranked by effect for clarity. Pearson correlation coefficient ($r$) and $P$-value (two tailed) suggest that sgRNAs targeting the same putative tumor suppressor elicit consistent and similar changes in size at 95\textsuperscript{th} percentile.

(B) Tumor sizes at the indicated percentiles for the top 17 tumor suppressor genes (relative to the average of sg\textit{Inert}-containing tumors) in \textit{KT;H11LSL-Cas9} mice. Error bars indicate 95\% confidence intervals. Dotted line indicates no effect. Percentiles that are significantly different from the average of sg\textit{Inerts} are in color. Data for all genes is shown in \textit{Supplementary Fig. S5B}. Pearson correlation coefficient ($r$) and $P$-value (two-tailed) for all sgRNA across all indicated percentiles are shown.

(C) The log-normal mean tumor size (normalized to tumors with sg\textit{Inerts}) for each putative tumor suppressor targeting sgRNA in \textit{KT;H11LSL-Cas9} mice. Error bars indicate 95\% confidence intervals. 95\% confidence intervals and $P$-values were calculated by bootstrap. sgRNAs that significantly increase or decrease tumor size are colored as indicated. sg\textit{Inerts} are in gray and the dotted line indicates no effect. Genes and sgRNAs are ordered as in \textbf{Fig. 2A}. The high Pearson’s correlation coefficient suggests that sgRNAs targeting the same putative tumor suppressor elicit consistent and similar changes in log-normal mean tumor size.

All plots represent aggregated data from 47 \textit{KT;H11LSL-Cas9}.

\textbf{Figure 3.} \textit{Stag2}, inactivation of which increases tumor burden and reduces survival, is frequently lowly expressed in human lung adenocarcinoma.
(A) Cre/lox-mediated Stag2 inactivation promotes Kras\textsuperscript{G12D}-driven lung tumor growth. Lung tumors were initiated in indicated genotypes of mice with Lenti-Cre and allowed to grow for 15 weeks.

(B) Representative fluorescence images of lung lobes from the indicated genotypes and genders of mice are shown. Scale bars = 5 mm.

(C) Lenti-Cre initiated tumors in indicated KT;Stag\textsuperscript{2floxflo} mice lack Stag2 protein expression. Scale bar = 50 mm.

(D) Lung weight from indicated genotypes of mice 15 weeks after tumor initiation with Lenti-Cre. Each dot represents a mouse and the bar is the mean. \(P\)-values were calculated by Student’s t-test.

(E) Inactivation of Stag2 increases lung tumor growth \textit{in vivo}. Representative histology is shown. Genotype and gender are indicated. Scale bars = 1 mm.

(F) Quantification of tumor area (\%) (tumor area/total lung area x 100) on H&E-stained sections of mouse lungs 15 weeks after tumor initiation. Each dot represents a mouse and the bar is the mean. \(P\)-values were calculated by Student’s t-test.

(G) Survival curve of mice with KrasG12D-driven lung tumors that are either Stag2 wild-type (KT;Stag\textsuperscript{2w/w} female and KT;Stag\textsuperscript{2w/y} male mice), Stag2 heterozygous (KT;Stag\textsuperscript{2flo/w}), or Stag2 deficient (KT;Stag\textsuperscript{2flo/flo} female and KT;Stag\textsuperscript{2flo/y} male mice). Mouse number, \(P\)-value and median survival (in days) are indicated. \(P\)-values were calculated by comparing each cohort to the Stag2 wild-type cohort (Mantel-Haenszel test).

(H) Representative STAG2 IHC on human lung adenocarcinomas expressing high (positive) or low (low and negative) STAG2 protein. Scale bars = 100 \(\mu\)m.
Quantification of STAG2 expression in 479 human lung adenocarcinomas. Data are grouped by tumor grade (left, with lower grade indicating well-differentiated tumors and higher grade indicating poorly differentiated tumors) or by tumor stage (right, classified by TNM staging system). A higher percentage of \( \text{Stag}^2 \text{low/neg} \) tumors are poorly differentiated (left) and more advanced (right) tumors.

Figure 4. Exaggeration of tumor phenotypes and emergence of more functional tumor suppressors over time.

(A) Schematic of tumor initiation with a pool of 85 barcoded Lenti-sgRNA/Cre vectors (Lenti-sgTS85/Cre) which excludes 8 tumor suppressor genes (in gray and crossed out) from the Lenti-sgTS102/Cre pool whose losses collectively account for ~60% of total tumor burden. Each gene is targeted with two sgRNAs. Mouse genotype, mouse number, and titer of lentiviral vectors delivered to each mouse are indicated. Tuba-seq was performed on each tumor-bearing lung at the indicated time after tumor initiation.

(B) Volcano plot of the impact of inactivating each putative tumor suppressor gene on relative tumor burden. Each dot represents an sgRNA. Genes for which both sgRNA increase tumor burden are colored.

(C,D) The impact of inactivating each gene on the size of the 95\(^{th}\) percentile tumor (C) and log-normal mean (D) at 15 weeks (Lenti-sgTS102/Cre 15 weeks) and 26 weeks (Lenti-sgTS85/Cre 26 weeks) after tumor initiation is shown. Each dot represents an sgRNA. Statistics are calculated from aggregating all tumors from 40 \( KT;H\text{I}1^{\text{LSL-Cas9}} \) (26 weeks) and 47 \( KT;H\text{I}1^{\text{LSL-Cas9}} \) (15 weeks) mice.
Figure 5. Tumor initiation is inhibited by diverse tumor suppressor genes independent of their effects on tumor growth.

(A) Inactivation of many tumor suppressor genes increases tumor number, highlighting pathways that normally constrain the earliest steps of carcinogenesis. The effect of each sgRNA on tumor number 15 weeks after tumor initiation with Lenti-sgTS102/Cre in KT;H11LSL-Cas9 mice is shown. Error bars indicate 95% confidence intervals. 95% confidence intervals and P-values were calculated by bootstrap. sgRNAs that significantly increase or decrease tumor number are colored as indicated. sgInerts are in gray and the dotted line indicates no effect. Genes and sgRNAs are ordered as in Fig. 2A.

(B) Genotype specific effects on growth (represented by the size of the tumor at the 95th percentile) and tumor number can be independent aspects of tumor suppression.
(C,D) Mutation frequency of members of the COMPASS complex in human lung adenocarcinoma.

Data are shown as the number of patients with mutations in one or more of the COMPASS complex subunits/total patient number from GENIE/IMPACT (C) as well as TCGA and TRACERx (D). Data from GENIE/IMPACT are based on panel sequencing and therefore does not include data on NCOA6. Data from TRACERx are from multi-region sequencing where we report the number of tumors that had any of these four genes mutated in one or more regions.

(E) The effect of each sgRNA on tumor number 26 weeks after tumor initiation with Lenti-sgTS85/Cre in KT;H11Lsl-Cas9 mice is shown. Error bars indicate 95% confidence intervals. 95% confidence intervals and P-values were calculated by bootstrap. sgRNAs that significantly increase or decrease tumor number are colored as indicated. sgInerts are in gray and the dotted line indicates no effect. Genes and sgRNAs are ordered as in (A).

(F) Effects of tumor suppressor gene inactivation on tumor number are highly reproducible. The impact of inactivating each gene on tumor number at 15 weeks (Lenti-sgTS102/Cre 15 weeks) and 26 weeks (Lenti-sgTS85/Cre 26 weeks) after tumor initiation is shown. Each dot represents an sgRNA. Statistics are calculated from aggregating all tumors from all mice in each group in each experiment. Pearson correlation coefficient (r) shows correlation.

**Figure 6. Loss of p53, Cdkn2a and Dnmt3a result in rare yet exceptionally large tumors.**

(A) Plot of tumor sizes for each indicated sgRNA in KT;H11Lsl-Cas9 mice at 15 weeks. Each dot represents a tumor and the area of the dot scales with neoplastic cell number within the tumor. For better visualization, an equal number of tumors (n=1160) are shown for each sgRNA.
Volcano plot of the impact of inactivating each putative tumor suppressor gene on the distribution of tumor sizes (Hill’s estimator compares tumors above the 95th percentile to those at the 95th percentile to quantify the relative size of tumors in the tail of the distribution). *P53*- and *Dnmt3a*-targeted tumors are heavy-tailed, suggesting that loss of these genes promoted the emergence of exceptionally large tumors. Each dot represents an sgRNA.

Plot of tumor sizes for each indicated sgRNA in *KT;H11LSL-Cas9* mice at 26 weeks. Each dot indicates a tumor, and the area of the dot indicates neoplastic cell number within the tumor. Equal number of tumors (814 tumors randomly sampled) are shown for each sgRNA.

Volcano plot of the impact of inactivating each putative tumor suppressor gene on the developing of infrequent exceptionally large tumors (Hill’s estimator). Each dot represents an sgRNA. Statistics are calculated from aggregating all tumors from 40 *KT;H11LSL-Cas9* (26 weeks) mice.

Inactivation of *Dnmt3a* and *Cdkn2a* generate tumor size distributions with heavy tails. Probability density plots for tumor sizes show the profile of aggregated tumors with sg*Inert* as well as individual sgRNAs targeting either *Dnmt3a* or *Cdkn2a*. Data is aggregated from all tumors from 40 *KT;H11LSL-Cas9* (26 weeks) mice.

Figure 7. Tumor suppressors constrain tumorigenesis at different stages and to different levels.

Radar plots of representative genes whose inactivation affects tumor size at the 95th percentile (relative to sg*Inert*, indicating increased overall growth), tumor number (relative to sg*Inert*,...
indicating increased tumor initiation) and Hill’s estimator (relative to sgInerts, indicating increased rare large tumors). Tumor suppressors suppress different aspects of tumor development.

(B) Heatmap summarizing the tumor size at the 95th percentile (relative to sgInerts), tumor number (relative to sgInerts) and Hill’s estimator (relative to sgInerts) of the functional tumor suppressor genes. Color scale is indicated on the side. Bolded circles indicate bootstrap P < 0.05. Although the sizes of Ubr5-, Tsc1-, Kdm6a- and Ncoa6-deficient tumors are not significantly different from control tumors at 95th percentile, they are significantly greater across multiple percentiles at 26 weeks, and thus they are also considered genes that suppress tumor growth.
